Abstract

ABSTRACT

Non-uniform memory access (NUMA) architectures pose numerous performance challenges for main-memory column-stores in scaling up analytics on modern multi-socket multi-core servers. A NUMA-aware execution engine needs a strategy for data placement and task scheduling that prefers fast local memory accesses over remote memory accesses, and avoids an imbalance of resource utilization, both CPU and memory bandwidth, across sockets. State-of-the-art systems typically use a static strategy that always partitions data across sockets, and always allows inter-socket task stealing.

In this paper, we show that adapting data placement and task stealing to the workload can improve throughput by up to a factor of 4 compared to a static approach. We focus on highly concurrent workloads dominated by operators working on a single table or table group (partitioned tables). Our adaptive data placement algorithm tracks the resource utilization of tasks, partitions of tables and table groups, and sockets. When an utilization imbalance across sockets is detected, the algorithm corrects it by moving or repartitioning tables. Also, inter-socket task stealing is dynamically disabled for memory-intensive tasks that could otherwise hurt performance.

Intro

1. INTRODUCTION

Processor vendors are scaling up modern servers by interconnecting multiple sockets in a single shared-memory system. Each socket has a memory controller and multiple cores attached, introducing new performance challenges for software. There are non-uniform memory access (NUMA) latencies across the system. The resources, either CPU or memory bandwidth, of a single socket, as well as the bandwidth of a single interconnect link, are additional bottlenecks to be considered. Contemporary main-memory column-store database management systems (DBMS), such as SAP HANA [11] or Oracle [23], need to tackle the challenges of data placement and scheduling in order to scale up on modern NUMA hardware and efficiently service highly concurrent big data analytics.

In order to balance utilization across sockets, state-of-the-art systems [16, 20] partition data across sockets and employ task scheduling with inter-socket task stealing. Our previous analysis of concurrent NUMA-aware scans [28] showed that such a static

Figure 1: A conceptual example of our adaptive data placement.

strategy for data placement and task scheduling can incur an overhead. Our adaptive data placement algorithm can help avoid this overhead.

Our proposed design relies on tracking the history of CPU and memory bandwidth utilization at three levels (see Section 5): (a) tasks, (b) partitions of tables and table groups, and (c) sockets. When the execution engine detects a utilization imbalance across sockets, it either moves or repartitions tables in order to fix the imbalance (see Section 6). Moreover, it also finds cold partitioned tables to consolidate and disallows inter-socket stealing of memory-intensive tasks that would hurt performance (see Section 7).

Figure 1 shows a conceptual example of the most significant aspects of our adaptive techniques. The server has four fully interconnected sockets. The server consists of numerous concurrent memory-intensive scans on three tables, which are initially placed on two of the server's sockets. Task stealing is disallowed due to the memory intensity of the scans. Two of the sockets are fully utilized, and their memory bandwidth is saturated, while the remaining two sockets are idle. Our adaptive data placement detects the utilization imbalance, and takes actions to fix it. It moves table *TBL2* to socket 3, partitions *TBL2* across sockets 2 and 4, and finally merges the unutilized parts of *TBL4*. Socket utilization becomes balanced. The total memory throughput is 2x higher than initially, improving the workload's throughput by 2x (see Section 8.1).

Contributions. In this paper, we present adaptive NUMA-aware techniques for main-memory column-stores. We adapt data placement and inter-socket task stealing to workloads dominated by operators working on a single table or table group (partitioned

>= 3
contributions

tables), at run-time. Our implementation and experiments are based on a commercial column-store (SAP HANA). Our contributions are:

- An adaptive data placement strategy that can improve throughput by up to 2x in comparison to a static strategy that always partitions data across all sockets. We present an adaptive heuristic algorithm that moves and repartitions tables at run-time in order to balance the utilization across sockets.
- Adapting inter-socket task stealing to the memory intensity of tasks, improving throughput by 1.1x–4x in comparison to a static strategy that always allows inter-socket stealing.
- To adapt data placement and task stealing, complete knowledge of the system's utilization is needed. We present a design that tracks the utilization history at the levels of (a) tasks, (b) partitions of tables and table groups, and (c) sockets.

2. BACKGROUND

In this section, we give a brief overview of NUMA-awareness, data placement and task scheduling in main-memory column-stores.

NUMA. Processor vendors scale up modern machines with a non-uniform memory access (NUMA) architecture. Figure 2a shows an example of a 4-socket server. Each socket has a 15-core Intel Xeon E7-4800v3 CPU. Each core has its own L1 and L2 caches, and a socket's cores share a L3 cache. Eight 16-GB DIMM are attached to each socket. The sockets are interconnected to exchange data requests and support cache coherence. In this example, each socket has 3 CPU links, forming a fully-interconnected topology (maximum of 1 hop across sockets). The topology, the interconnects, and the cache coherence protocol are specific to each system.

NUMA-awareness. Since memory is distributed, new performance challenges arise for software: (a) accesses to remote memory can be up to 5x slower than local memory, (b) the bandwidth of a socket and an interconnect can be up to 7x lower than the bandwidth of a socket [7, 29]. Due to the lack of knowledge about inter-socket routing or the cache coherence, a NUMA-aware application attempts to solve the above challenges in a simple way: optimizing for local memory accesses instead of remote accesses, and avoiding unnecessary centralized bandwidth bottlenecks.

Memory management in the operating system. The OS organizes memory with (typically) 4-KB pages [17]. The physical location of a virtual memory page, which an application has allocated, is decided upon the first page fault. In Linux, the default “first-touch” policy attempts to allocate physical memory for a virtual page on the socket where the thread is running. Linux provides NUMA-aware

functions for an application, such as `mbind` or `move_pages`, to set and get the physical location of its allocated virtual memory.

Main-memory column-stores. The data of a column can be stored sequentially in a vector in main-memory (e.g., [18, 20, 23]). Compression techniques, such as dictionary encoding, are typically used to reduce the amount of memory and potentially speed up processing [21]. A generic dictionary-encoded column is composed of an integer vector, called *indexvector* (*IV*) (naming can be different), that stores *value IDs* (*vids*), and the *dictionary* vector, that stores the sorted unique real values of the value *IDs* [28].

Figure 2b shows an example of the physical location of the virtual memory of two tables with one column each. Assuming the same data type and page-aligned allocations, the example hints that Table 2 has around triple number of rows than Table 1 with a similar number of unique dictionary values. The DBMS has used OS NUMA-aware functions to place Table 1 on Socket 1 and Table 2 on Socket 2.

Data placement. An entire table can be placed on one socket as in Figure 2b, or can be physically partitioned across several sockets [1, 23]. By using, e.g., hash, range, or round-robin partitioning, we can define multiple *table parts* (*TBP*) [28]. All TBP share the same set of columns, but each column in a table part has its own *IV* and dictionary. As such, a table part can be entirely placed on one socket.

Task scheduling. With task scheduling, operators are encapsulated in tasks, which are put into task queues, and pools of worker threads are used to process them. The task scheduler can reflect the NUMA topology of a machine [16, 20, 27, 29]. In our previous work, we detailed our NUMA-aware task scheduler [27, 28]. We showed how stealing and a concurrency “hint” can help to saturate CPU resources without unnecessary scheduling overhead and that stealing memory-intensive tasks can hurt performance. In this work, we adapt task stealing to a task's memory intensity (see Section 7).

3. RELATED WORK

We organize related work by static NUMA-aware solutions, adaptive solutions, black-box solutions, and work on distributed systems.

Static solutions. Most DBMS not mentioning advanced NUMA optimizations indirectly rely on the static first-touch policy for data placement, e.g., *Vecorwise* [39], *Microsoft SQL Server's* column-store [19], or *IBM DB2 BLU* [30]. In a recent thesis describing how to parallelize query plans in *Vecorwise* with task scheduling [14], inter-socket stealing is allowed based on task priorities and the content of the sockets. In this work, we show that stealing should not be allowed for memory-intensive tasks. On the other hand, a distributed manager decides the NUMA location of columnar data when the topology changes [23], but not when the workload changes. *HyPer* [20] checks access patterns and statically decides their locality over the sockets, while inter-socket stealing is always enabled.

There is also related work on NUMA-aware standalone operators. *Albatrus* et al [5] construct a NUMA-aware sort-merge join. *Hash-joins*, however, are shown to be superior [6, 18]. *Yin et al* [12] optimize data shuffling. Most related work, however, optimize for low concurrency with a static data placement using all sockets of the server. In this work, we optimize for highly concurrent workloads, with a data placement that adapts to the workload.

Adaptive solutions. Two state-of-the-art research prototypes use an adaptive NUMA-aware solution for data placement: *ERIS* [16] and *ATraffix* [26]. *ERIS* is a storage manager that employs adaptive range partitioning, and each partition is assigned to a worker thread. While *ERIS* targets storage operations, we target analytical workloads consisting of numerous operators. In addition, we show in this paper

and sockets. We ignore on purpose stolen tasks. The utilization of sockets that steal appear non-saturated in our metrics, as stealing is a temporary solution to balance CPU load until our adaptive data placement algorithm (see Section 6) fixes the imbalance of local utilization. In the example of Figure 4, we depict how the average memory TP of a task class is used when scheduling a new task to aggregate the utilization at a

value is periodically sampled into a list of pairs of timestamps and values. We maintain one background *refresher thread* per socket, that periodically calls `sample()` on the histories of its socket and of a subset of all TBP and TGP. `sample()` appends a pair with the current timestamp and value to the back of the samples list, and increments the entries. If the entries grow over a specified limit, it removes the pair at the front of the list. In our current implementation, the refresher thread runs every 100 ms, and the limit of the samples

6.1 Abstract Workflow

The main component of our adaptive data placement is the *Data Placer (DP)* thread. Figure 6 shows its abstract workflow. The first time tables are loaded into memory, they can be placed across sockets in a round-robin manner. DP runs periodically in the background to monitor the workload, and automatically takes care to either move or repartition tables to fix a utilization imbalance.

DP focuses on balancing CPU utilization, under the constraint of not creating a memory bandwidth bottleneck. We remind that we refer to local-only utilization as tracked in Section 5. We balance the utilization between sockets with saturated CPU resources and colder sockets, by moving or partitioning tables. This strategy allows tables that were previously on saturated sockets to potentially increase their utilization using free threads on colder sockets (due to intra-query parallelism), increasing the total system utilization. At every period, DP gets a snapshot of the active RUH of TBP and TGP, and their recent utilization. It then calculates their eligibility for moving and partitioning, depending on whether their past utilization has been stable. Then, DP sorts the RUH within each socket by their recent utilization, aggregating them as well to calculate the recent utilization of the sockets. Afterwards, DP calculates the CPU utilization imbalance between all pairs of sockets, and sorts the pairs. For every pair of sockets, DP investigates whether a new placement can reduce the imbalance. DP proceeds only if the imbalance is over a threshold, and if the hot socket is saturated. If the hot socket is not saturated, the TBP and TGP cannot increase their utilization by exploiting free threads on the cold socket. DP iterates the RUH of the hot socket, and examines whether moving or partitioning an eligible RUH's owner (the corresponding TBP or TGP) reduces the imbalance. If additionally it does not create a memory bandwidth bottleneck, DP proceeds to move or partition the RUH's owner.

The outlined steps in Figure 6 are first executed while considering moving an eligible RUH's owner. If none can be moved across all socket pairs, we repeat the steps considering partitioning an eligible RUH's owner. This ensures we first prefer moving over partitioning, to avoid an unnecessary partitioning (see line 4). In our implementation, we use a simple mock-up table to start-up by moving or partitioning a simple mock-up table to another socket, without a concurrent workload. See Table 2 for the speeds of the machines we use in our experiments. The speeds are rough estimates. One can improve accuracy by specializing the speeds by socket, or the concurrent workload, or a table's characteristics such as the number of columns, data types, etc. However, we do not need to be precise, since the aim of our eligibility calculations is to disallow instant actions by DP and not delaying them for long. In our implementation, queries need to wait while a TBP is moved. We use SAP HANA's functionality to unload a TBP from memory and reload it on the desired socket. We do not use Linux's `move_pages`, because it would mess up the statistics of SAP HANA's NUMA-aware memory allocators [35]. Due to queries waiting during the move, we double the time to look in the past (line 5). This is optional and simply prolongs the amount of time to look in the past. Conceptually, the additional time corresponds to the time required to "recover" the utilization which drops to zero during the move. We then calculate the average past utilization of both CPU and memory TP (lines 6–7). The RUH is eligible for moving if the past utilization is within a threshold of the recent utilization (line 8).

The algorithm then continues similarly for calculating the eligibility of partitioning (lines 9–14). There are three differences. First, we require that the RUH is also eligible for moving (line 9). This is to enforce the preference of DP to having first considered moving the

Figure 6: Abstract workflow of the Data Placer (DP).

Next, we detail how the eligibility of RUH is calculated (see Section 6.2), how we reduce the utilization imbalance by moving or partitioning (see Section 6.3), and how we use the values we use in our experiments.

Table 1: Configurable parameters used in our algorithms, along with the values we use in our experiments.

Symbol	Description	Our value
c_p	Period of the Data Placer (DP) algorithm	1 second
e_r	Eligibility threshold for the divergence between the past and recent utilization of a RUH	30%
e_i	Acceptable imbalance threshold between the utilization of a pair of sockets	40% of socket cores
e_s	Lower threshold for considering a socket's utilization saturated	70% of socket cores

We assume that each socket corresponds to a NUMA node [17], and that all sockets have the same number of HW threads and maximum memory TP. This assumption is for typical NUMA servers with the same processors, and the same number and type of DIMM.

6.2 Information and Eligibility of RUH

At every period, DP finds the RUH of all TBP and TGP, takes a snapshot of their recent utilization and calculates their eligibility to be moved or partitioned. For every RUH, this information is stored in an *InfoRUH* object, which is defined in Algorithm 1, and calculated through the function `calcInfoRUH`. The algorithm first stores the recent CPU and memory throughput utilization of the RUH (lines 2–3). The RUH is deemed active if its utilization is non-zero (line 4). DP continues to calculate the eligibility of the RUH for moving or partitioning. A RUH is deemed eligible if its average utilization in the past does not diverge much from its recent utilization. The amount of time we look in the past depends on the implementation of the move or partition operation.

For the time to look in the past in the case of moving, we first calculate the time required to move the RUH's owner (line 5), by multiplying its pages with the speed of moving (microseconds per page). The speed of moving and partitioning are calculated at start-up by moving or partitioning a simple mock-up table to another socket, without a concurrent workload. See Table 2 for the speeds of the machines we use in our experiments. The speeds are rough estimates. One can improve accuracy by specializing the speeds by socket, or the concurrent workload, or a table's characteristics such as the number of columns, data types, etc. However, we do not need to be precise, since the aim of our eligibility calculations is to disallow instant actions by DP and not delaying them for long.

In our implementation, queries need to wait while a TBP is moved. We use SAP HANA's functionality to unload a TBP from memory and reload it on the desired socket. We do not use Linux's `move_pages`, because it would mess up the statistics of SAP HANA's NUMA-aware memory allocators [35]. Due to queries waiting during the move, we double the time to look in the past (line 5). This is optional and simply prolongs the amount of time to look in the past. Conceptually, the additional time corresponds to the time required to "recover" the utilization which drops to zero during the move. We then calculate the average past utilization of both CPU and memory TP (lines 6–7). The RUH is eligible for moving if the past utilization is within a threshold of the recent utilization (line 8).

The algorithm then continues similarly for calculating the eligibility of partitioning (lines 9–14). There are three differences. First, we require that the RUH is also eligible for moving (line 9). This is to enforce the preference of DP to having first considered moving the

Algorithms

Algorithm 1 Calculate information and eligibility of a RUH

14:   canPartition ← ((recentCpu - pastCpu) <  $c_p$ ) and (recentCpu > 0)
```

RUH's owner before considering partitioning it. Second, the amount of time to look in the past consists of partitioning plus the time required to move the new partitions to the correct sockets (line 11). We use SAP HANA's partitioning commands, which, contrary to the implementation of moving, creates the partitions in the background and allows queries [1]. Third, we limit the number of new partitions to the number of sockets to avoid excessive partitioning (line 9).

We note that in this work when we mention a TBP or TGP, we partition the corresponding table or TG into double their previous number of partitions. The reasons why we double the partitions are two. First, partitioning is more time-consuming than moving. Since we decide to partition, we `unpartition` the existing number of partitions and then `partition` again. This is usually faster than moving is, because moving requires `move` and `unmove` operations. Second, we want to ensure that the number of partitions is stable in the future (see Section 6.3 for a relevant experiment).

Conceptual figures

Figure 7: Conceptual examples of calculating the partitioning eligibility of (a) an ineligible RUH, and (b) an eligible RUH.

6.3 Reducing the Utilization Imbalance

The purpose of balancing the CPU utilization between sockets is to allow tables to increase their utilization by exploiting free threads on cold sockets when moved or partitioned out of saturated sockets. When considering moving or partitioning a table, however, we assume the worst case that it does not increase its utilization. This allows us to be on the safe side when calculating the new utilization imbalance, and truly decrease it with every move or partition.

saturates the interconnect network and overwhelms the already saturated memory controller. The overhead memory controllers achieve much lower overall memory TP (for both local and remote tasks) than the case of disallowing scaling.

As it increases, the workload becomes more CPU-intensive, and the memory TP of the system and the task class finally saturates. The overall system memory TP is 0.83 on the 4-socket server for the case when scaling is disabled, it starts at 0.83 and gradually increases up to 1.25 (for $n = 30$). At a switching point, scaling becomes better, and remote tasks can be satisfied through the interconnect, and the memory TP of the system is 1.25. At the next switching point, the remote tasks can't meet the memory TP of the task class as the threshold for stealing vs. no stealing. Our adaptive task stealing uses this threshold at run-time. If the exponential average of a task class becomes higher than the threshold, scaling is disallowed for tasks of the task class. On the other hand, if the exponential average becomes lower than the threshold, scaling is allowed.

8. EXPERIMENTAL EVALUATION

We first present our experimental configuration. Then, we present the results of a custom benchmark and finally of the TPC-H benchmark.

Experimental configuration. We use a prototype built on SAHANA (SPS1), a commercial main-memory column-store, with our NUMA-aware task scheduler and scans [28]. We add support for more NUMA-aware operators (see Section 4), track resource utilization (see Section 5), and employ our adaptive NUMA-aware data placement (see Section 6) and task stealing (see Section 7).

For all experiments, we warm up the DBMS, we admit all clients and disable result caching. LLC misses, CPU load, and memory

(a) `SELECT COLx FROM TBly WHERE COLx >= ? AND COLx <= 7`. The client selects a random column from its target table. The query involves both scan phases mentioned in Section 4.

(b) `SELECT COL1, SUM(CTO_DOUBLE(COLx)) FROM TBly WHERE COLx = ? AND COLx <= ? GROUP BY COL1`. The client selects a random column (COL2-8) from its target table to aggregate and group-by COL1. This query involves the aggregation phases mentioned in Section 4. We choose COL1 for the group-by because it has the least number of unique values. We cast to double to avoid potential numeric overflow errors.

(c) `SELECT TBLz.COLx FROM TBLy, TBLz WHERE TBLy.ID = TBLz.ID AND TBLy.COLx >= ? AND TBLy.COLx <= ?`
The client joins two target tables on the ID column. A random column is selected to filter and project. This query involves the equi-join steps mentioned in Section 4.

Before each experiment begins, we let clients build a prepared statement for each query they can issue. There are no thinking times. The clients do not fetch results, in order to not let the network transfer dominate. Each TP value in a timeline corresponds to the slope of the achieved queries during the previous 30 seconds.

The first experiment relates the introductory example of Figure 1. T_{BL1} and T_{BL2} are placed on socket S1, T_{BL3} on S2, and T_{BL4} is partitioned across S3 and S4. Each of the tables T_{BL1} – T_{BL4} are targeted by a query that is only executed once, and the total execution time is 5 minutes. Figure 10 shows the timelines of the throughput (TP), the utilization imbalance, and additional performance measurements that include HW counters as well as our tracked utilization (RH, CPU, and I/O) for each of the four queries. The queries are R_{BL} , R_{UH} . Queries are dominated by the scan's first phase ("Pre-Scan") as queries are memory-intensive as shown by the task's memory ("Mem") which is over the scaling threshold. That is why adaptive scaling is not needed. The queries are memory-intensive because they access all tables R_{BL} , T_{BL1} and T_{BL2} share S1, while T_{BL3} fully utilizes S2. DP recognizes the imbalance, but does not take action because the TBP are not yet eligible to be moved or partitioned. The searches for the optimal partitioning are shown in Figure 11. The results are shown in Figure 10, and at 16 s starts a background request to merge it. The merge finishes at 4 s, and the simple TBP is moved to S4 to cold socket at 10 s. The merge and move contribute to the small bump in the throughput. The throughput is not affected by the move as their increased CPU load is that their workers threads attempt to steal tasks from other sockets, but these are memory-intensive and cannot be moved. The throughput is not affected by the move as the queries are queries, we do not account this busy CPU load in their RH, CPU, and I/O.

At 53 s (see markers on the timeline of the tables' RUH graphs), DP examines the pair of S1 and S3. It decides to fix their imbalance by moving TBL2, which has become eligible for moving, to S3. The move completes at 91 s. Overall TPI and memory TPI are increased.

Next, DP detects that there is still a utilization imbalance because 3 sockets are utilized and S4 is not (as shown by its RUH). At 108 s, DP examines the pair of S2 and S4. It decides to fix their imbalance by partitioning TBL3, which is eligible for partitioning, into two parts. At 174 s, partitioning completes, and the two TBP are moved to S2 and S4 concurrently, which completes at 190 s.

After that point, the imbalance is decreased within our threshold, and there are no more actions. In comparison to the beginning of the experiment, overall memory TP is 2x more, and TP is also 2x more

Figure 10: Introductory experiment showing the adaptive data placement.

To show the effect of adaptive task stealing, we use scans of varying selectivity. We place TBL1 on S2 and TBL2 on S4. Adaptive placement is disabled. Each of the tables is targeted by 256 client executing query (a) with the specified selectivity. Half of the sockets have local tasks, while the other half would need to steal. For each selectivity, we execute 5 min runs of: enabled stealing for all tasks; disabled stealing for all tasks, and adaptive stealing. We report each run's average TP. The results are shown in Figure 11.

Figure 11: Experiment showing how adaptive task stealing disallows stealing of memory-intensive classes (4-socket server).

For low selectivities, the scan's first phase ("TV-scan") dominates. Tasks are memory-intensive and stealing hurts TP by up to 23% for the case of 0.1% selectivity. As selectivity increases, the scan's second phase (materialization) dominates and is parallelized. The

fewer I-Scan tasks can utilize more memory bandwidth on their socket. The dominating materialization tasks are CPU-intensive, due to their random accesses to the dictionary, and thus stealing helps improve TP by up to 70% for the case of 10% selectivity. Adaptive stealing achieves the best TP of either stealing or not stealing in all cases of selectivity. It can also, e.g., for the case of 1% selectivity further improve performance by 15%. This is due to disallowing stealing of I-Scan tasks, and allowing stealing of materialization tasks. Instead of taking a static strategy for all task classes.

Here, we show how our adaptive data placement can avoid the overhead of unnecessary partitioning. We focus on aggregation queries, which are similar for join queries across all sockets. For example, for a query with a join across all sockets, the overhead of partitioning is unnecessary. The overhead of partitioning is unnecessary for a query with a join across all sockets. The overhead of partitioning is unnecessary for a query with a join across all sockets.

Configuration

Conclusion and references

Priorities and fairness. Priorities and fairness are an orthogonal issue out of this paper's scope. We note that our task scheduler supports priorities and a degree of fairness (based on query submission time) [28]. In typical cases, if a workload has user-defined priorities, the prioritized tasks will highly contribute to the utilization of RUH which will be considered first by DP for moving or partitioning.

Task classes. Tasks in the same class should have similar memory throughput. We assume that classes are defined manually, as we do in Section 5 for our NUMA-aware operators. One can further specialize classes, e.g., by the involved predicates. As seen in Section 7, an aggregation's memory throughput can vary depending on the complexity of the predicate. Ideally, we need a way to classify complex predicates. This is left out of the paper's scope. For our implementation and experiments, we use rather typical predicates and the defined task classes can sufficiently capture the memory intensity of our NUMA-aware operators' different phases.

Unit of data placement. Our unit of data placement is a row-wise partition of a table. An alternative would be column-wise partitioning, i.e., placing a table's columns on different sockets. In such a case, a global dictionary (see Section 4) is not needed, but queries referencing columns on multiple sockets incur a lot of remote accesses. For this work, we assume that the organization of associated columns into tables is left to the administrator.

Balancing memory throughput. We balance primarily the CPU utilization under the constraint of not creating memory bandwidth hotspots. This is to allow newly placed data to potentially increase their utilization. Since we balance local-only CPU utilization, this can indirectly balance memory TP as well as shown in many of our experiments. This is not guaranteeing, however. One may wish DP to continue balancing memory TP after CPU utilization is balanced under the constraint of not increasing the CPU imbalance. DP's possible actions can be extended to consider exchanging TBP or TGP between sockets. We have found only a few cases where balancing memory TP is required to slightly improve IPC and TP.

10. CONCLUSIONS

In this paper, we show that main-memory column-stores should not employ a static strategy of always partitioning data across all sockets, and always allowing inter-socket task scaling. We show that unnecessary partitioning involves an overhead of up to 2x in comparison to not partitioning. For this reason, we develop an adaptive data placement algorithm that can track a utilization imbalance across sockets, and can move or repartition tables at run-time to fix the imbalance. Also, we show that inter-socket stealing of memory-intensive tasks can hurt throughput by up to 4x in comparison to not stealing. For this reason, we develop an adaptive technique that disables scaling at run-time for tasks whose memory intensity exceeds a fixed threshold for a NUMA server.

Final summary and takeaway

Submission and reviews

Typical timeline:

- Prepare paper for months ahead of deadline
- Submit by deadline (e.g., Microsoft CMT)
- Submit conflicts of interest of authors
- Get (blind) reviews a couple of months later
- Possible rebuttal phase
- Acceptance/rejection notification
- If accepted, camera-ready deadline
- Copyright form
- At least 1 presented live in the conference
- Prepare presentation & do dry-runs
- Travel typically paid by academic institution
- Present & possible poster session

VLDB 2025: Important Dates

All deadlines below are 5 p.m. PT, unless otherwise noted.

	Chairs	Submissions Open	Submissions Deadline	Notifications	Camera-Ready Submissions
Research Track	Themis Palpanas University Paris Cité Nesime Tatbul Intel Labs and MIT	20 th of every month starting March 2024	1 st of every month until March 2025	15 th of the next month following the deadline	Proceedings chairs will contact the authors with CR instructions by the 5 th of the next month following the acceptance notification
Industrial Track	Surajit Chaudhuri Microsoft Research, USA Nikos Ntarmos Huawei, United Kingdom Jingren Zhou Alibaba Group, China	TBD	March 17, 2025	May 19, 2025	July 14, 2025
Tutorials	Hakan Ferhatosmanoglu University of Warwick and AWS Madelon Hulsebos CWI	TBD	April 15, 2025	May 30, 2025	Camera-ready: July 1, 2025 Slides availability: August 20, 2025

20' incl. Q&A

Core experiments

Adaptive NUMA-aware data placement and task scheduling for analytical workloads in main-memory column-stores

Iraklis Psaroudakis* (Oracle), Tobias Scheuer (SAP), Norman May (SAP), Abdelkader Sellami (SAP), Anastasia Ailamaki (EPFL)

* work done while at EPFL and SAP

Stealing tasks with high memory throughput
4x15-core Intel Xeon E7-4880v2, 190 columns, 100GB
1024 clients selecting a column with 0.001% selectivity, half of column hotter

Do not steal memory-intensive tasks

NUMA: Non-Uniform Memory Access

4x15-core Intel Xeon E7-4880v2, 16GB DDR3, QPI interconnects

Synergistic data placement and scheduling

Adaptive placement in practice

4x15-core Intel Xeon E7-4880v2, 10 GB
Each table targeted by 64 clients that select a column with 0.001% selectivity

Explain with timeline

Talk through visual cues

Battling workload skew

Are stealing and partitioning always good?

No...

Punchlines

Conclusions

- Do not always partition data & steal tasks
- Task stealing can hurt performance by 4x
 - Adapt: do not steal memory-intensive tasks
- Unnecessary partitioning can hurt performance by 2x
 - Adapt: first move data before partitioning in order to balance utilization

Few words, concise takeaways

You tell the story over the poster

Adaptive NUMA-aware data placement and task scheduling for analytical workloads in main-memory column-stores

Iraklis Psaroudakis* (Oracle), Tobias Scheuer (SAP), Norman May (SAP), Abdelkader Sellami (SAP), Anastasia Ailamaki (EPFL)

* work done while at EPFL and SAP

1. NUMA-awareness

- Modern servers: non-uniform memory access (NUMA)
- e.g., 4x15-core Intel Xeon E7-4880v2, 16GB DDR3, QPI

Synergistic data placement and scheduling

5. Tracking the workload's utilization

Local utilization only

RUN = resource utilization history (sampled)

2. Data and scheduling in a column-store

How to place data and when to steal tasks?

6. Adaptive task stealing (utilization placement)

- Find matching point of means, intensity for allowing task stealing
- Compute $\sum_{i=1}^n (v_i / \mu)$ of all vectors. Vectors placed on half of sockets.
- Machine: 8x15-core Intel Xeon E7-4880v2
- w/o stealing → w/o stealing → w/o stealing

3. Workload skew

Round robin (RR) placement

Physical partitioning (PP) placement

Task stealing and data partitioning battle workload skew

4. Overhead of stealing & partitioning

Bind mem-intensive tasks

Do not partition unnecessarily

7. Adaptive data placement

Periodically move & partition data to balance sockets' local utilization.

Place tables with RR

8. Adaptive data placement in action

Conclusion

- Software developer life in academia & research involves
 - 35% coding
 - 35% experimenting, writing
 - 15% reading related work
 - 15% talking, presenting, getting feedback
- More flexibility and challenging topics than industry
- Less life-work balance than industry
- Publish or perish
- Experimental evaluation is key
- Presenting in a succinct manner is key
- PhD necessary for academia, wished for in R&D, not necessary for industry
